### SLOS574B –SEPTEMBER 2008–REVISED MAY 2010 **www.ti.com**

Alle

This integrated circuit can be damaged by ESD. Texas Instruments recommends that all integrated circuits be handled with appropriate precautions. Failure to observe proper handling and installation procedures can cause damage.

ESD damage can range from subtle performance degradation to complete device failure. Precision integrated circuits may be more susceptible to damage because very small parametric changes could cause the device not to meet its published specifications.

**Figure 30. LVDS Eye Pattern**

# **APPLICATION INFORMATION**

## **THEORY OF OPERATION**

The AFE5851 is a low power CMOS monolithic analog front end that includes a 16-channel variable gain amplifier (VGA) followed by an 8-channel 12-bit high speed pipeline analog to digital converter (ADC) based on switched capacitor architecture.

Each of the 16 VGA single ended inputs is buffered and accepts a maximum swing of  $1V_{PP}$  centered at a DC level (VCM) of about 1.6V.

Each VGA has a gain range from –5dB to 31dB and it is digitally controlled, with a resolution of 0.125 dB. The gain curves (common to all VGAs) versus time can be stored in memory integrated within the device using the serial interface.

A hardware sync input pin is available (SYNC). When a pulse is applied to this pin, all the VGAs in the device start stepping through the selected time-gain curve at the same clock cycle. This sync can also be initiated by software using the serial interface.

A selectable anti-alias low pass filter (AAF) with 6 dB attenuation at 7.5MHz, 10MHz or 14MHz, is also integrated, together with clamping (which can be disabled).

The VGA/AAF can output  $2V_{PP}$  differential swing without degradation in the specified linearity, and drive an on-board 12-bit ADC shared between two VGAs to optimize power dissipation. Each VGA output is sampled at the rising edge of alternating clock cycles, making the effective sampling frequency half the input clock rate. For instance, in order to sample each analog channel at 30 MSPS, the input clock frequency needs to be 60 MHz. This effectively introduces a half (sampling) clock delay between the sampling instants of the two analog channels.

After the input signals are captured by the sample and hold circuit, the samples are sequentially converted by a series of low resolution stages. The stage outputs are combined in a digital correction logic block to form the final 12-bit word with a latency of 11 clock cycles (without taking into account the delays introduced by the optional digital signal processing functions). The 12-bit words of each channel are serialized and output as LVDS levels in straight offset binary format. In addition to the data streams, a bit clock and frame clock are also output. The frame clock is aligned with the 12-bit word boundary.

Notice that for the correct operation of the device (see Serial Interface Section) a positive pulse must be applied to the Reset pin. This sets the internal control registers to zero. There is, nevertheless, no need for any type of power-up sequencing.

### **INPUT CONFIGURATION**

The analog input for the AFE5851 [\(Figure](#page-15-0) 31) consists of an analog buffer input gate biased to a value of 1.6V (usually referred as voltage common mode, VCM). The biasing is done with an internal resistor of 5kΩ. For proper operation, the input signal should be in the recommended input range. The maximum input swing is limited to  $1V_{PP}$  before distortion/saturation of the input stage occurs. As the input DC level (VCM) is about 1.6V, the input of the VGA should stay between 1.1V and 2.1V. If the information in the low frequencies of the signal is irrelevant AC coupling can be used. As the input capacitor forms a high-pass filter with the internal bias resistor (5kΩ), the value of the capacitor should allow the lowest frequency of interest to pass with minimum attenuation. For the typical frequencies used in ultrasound (>1MHz) a value of 10nF or greater is recommended. If DC coupling is preferred, the user can tap the VCM output pins to set the DC level of the input signal. VCM output should be connected to high input impedance circuits as its driving capability is limited. Regardless of the chosen input configuration, a capacitor of 100nF should be connected on each VCM input to AVSS.

**Figure 31. Input Equivalent Circuit**

## <span id="page-15-0"></span>**SERIAL INTERFACE**

#### **Register Initialization**

After power-up, the internal registers must be initialized to the default value (zero). Initialization can be done in one of two ways:

- 1. Through a hardware reset, by applying a positive pulse in the RESET pin
- 2. Through a software reset, using the serial interface, by setting the SOFTWARE RESET bit to high. Setting this bit initializes the internal registers to the respective default values (all zeros) and then self-resets the SOFTWARE RESET bit to low. In this case, the RESET pin can stay low (inactive).

#### **Reset Timing**

Typical values at 25°C, min and max values across the full temperature range  $T_{MIN} = -40^{\circ}C$  to  $T_{MAX} = 85^{\circ}C$ , AVDD3 = 3.3V, AVDD18 = DVDD18 = 1.8V unless otherwise noted.

**Figure 32. Reset Timing Diagram**

Programming of different modes can be done through the serial interface formed by pins SEN (serial interface enable), SCLK (serial interface clock), SDATA (serial interface data) and RESET. SCLK and SDATA have a pull-down resistor to GND of 100kΩ and SEN has a 100kΩ pullup resistor to DVDD18. Serial shift of bits into the device is enabled when  $\overline{SEN}$  is low. Serial data SDATA is latched at every rising edge of SCLK when  $\overline{SEN}$  is active (low). The serial data is loaded into the register at every 24th SCLK rising edge when SEN is low. If the word length exceeds a multiple of 24 bits, the excess bits are ignored. Data can be loaded in multiple of 24-bit words within a single active  $\overline{\text{SEN}}$  pulse (there is an internal counter that counts groups of 24 clocks after the falling edge of  $\overline{SEN}$ ). The interface can work with the SCLK frequency from 20 MHz down to low speeds (few Hertz) and even with non-50% duty cycle SCLK.

The data is divided into two main portions: a register address (8 bits) and the data itself, to load on the addressed register (16bits). When writing to a register with unused bits, these should be set to 0. The following timing diagram illustrates this process:

**Figure 33. Serial Interface Register Write**

**NSTRUMENTS** 

ÈXAS

Minimum values across the full temperature range,  $T_{MIN} = -40^{\circ}C$  to  $T_{MAX} = 85^{\circ}C$ , AVDD3 = 3.3V,  $AVDD18 = DVDD18 = 1.8V$ .

### **General Purpose Register Map**

The internal registers can be divided into two groups. A group of registers to control all the general functions and settings of the device, and a bank of registers to control the TGC/gain curves operation. Those two sets of registers overlap in all the address space, except for the address 0 which holds the control of the register bank. One of the bits of this register, TGC\_REG\_WREN (see table below) is used to access one set of registers or the other. Its default value is zero and gives access to the general purpose registers. The TGC control registers (described after the general purpose registers) can be accessed by writing '1' to TGC\_REG\_WREN.

The following table describes the function of the general purpose registers (when TGC\_REGISTER\_WREN is zero, default). The address format is "address[bit of the register]":

<span id="page-17-0"></span>

18 Submit [Documentation](http://www.go-dsp.com/forms/techdoc/doc_feedback.htm?litnum=SLOS574BB&partnum=AFE5851) Feedback Copyright © 2008–2010, Texas Instruments Incorporated

### <span id="page-19-0"></span>**General Purpose Register Description**

#### **AVERAGING\_ENABLE**

#### Address: 2[11]

When set to one, two samples, corresponding to two different channels on the same pair, are averaged (channel 1 with 3, 2 with 4, 5 with 7, 6 with 8, 9 with 11, 10 with 12, 13 with 15 and 14 with 16). If both channels receive the same input, the net effect is an improvement on SNR. The averaging is performed as:

- 1. Channel 1 with channel 3 comes out on channel 3 LVDS pair, followed by the average of channels 2 and 4 (on the same pair).
- 2. Channel 5 with channel 7 comes out on channel 4 LVDS pair, followed by the average of channels 6 and 8 (on the same pair).
- 3. Channel 9 with channel 11 comes out on channel 5 LVDS pair, followed by the average of channels 10 and 12 (on the same pair).
- 4. Channel 13 with channel 15 comes out on channel 6 LVDS pair, followed by the average of channels 14 and 16 (on the same pair).

#### **CUSTOM\_PATTERN**

Address: 5[13:0]

This register stores the code that will be output when PATTERN\_MODE equal to '011'. See PATTERN MODE for more details.

#### **DFS**

#### Address: 4[3]

DFS stands for Data Format Select. The ADC output, by default, is in 2s complement mode. Programming the DFS bit to '1' inverts the MSB, and the output becomes straight offset binary mode.

#### **DIGITAL\_GAIN\_ENABLE**

#### Address: 3[12]

Setting this bit to '1' applies to each channel I the corresponding gain given by DIG\_GAIN<sub>i</sub><15:11>. The gain is given as  $0dB+0.2dB*DIG_GAlN<sub>i</sub><15:11>$ . For instance, if DIG\_GAIN $<sub>5</sub><15:11>=3$ , channel 5 is increased by</sub> 0.6dB gain. DIG\_GAIN<sub>i</sub><15:11>=31 produces the same effect as DIG\_GAIN<sub>i</sub><15:11>=30 setting the gain of channel i to 6dB.

#### **DIGITAL\_HIGH\_PASS\_FILTER and DIGITAL\_HIGH\_PASS\_FILTER\_CORNER\_FREQ**

Address: 21[0] Address: 33[0]

Address: 21[4:1]

Address: 33[4:1]

This group of 4 registers controls the characteristics of a digital high pass transfer function applied to the output data, following the formula:  $y(n) = 2^k/(2^k + 1) [x(n) -x(n-1) + y(n-1)]$ . K is set as described by the DIGITAL\_HIGH\_PASS\_FILTER\_CORNER\_FREQ registers (one for the first 8 channels and one for the second group of 8 channels).

#### **EXTERNAL\_REFERENCE**

#### Address: 1[13]

Internal reference mode (default) uses approximately 3mW more power on AVDD (already included in all the specification tables). The AFE5851 can operate in external reference mode by programming EXTERNAL\_REFERENCE to '1'. In this mode, drive the VREF\_IN pin with 1.4V. Due to the high input impedance of this pin, no special drive capabilities are required. The advantage of using the external reference mode is that multiple AFE5851 units can be made to operate with the same external reference, thereby improving parameters such as gain matching across devices.

#### **FILTER\_BW**

Address: 7[3:2] This bit sets the 3dB attenuation frequency for the anti-aliasing filter (AAF).

#### **GLOBAL\_PDN**

#### Address: 1[0]

The Global PDN bit is ORed with the signal in the external PDN pin (59). Hereby, a '1' on this bit shuts down the device completely.

### **INTERNAL\_AC\_COUPLING**

#### Address: 7[1]

This bit controls an internal high pass filter, [Figure](#page-15-0) 31, set between the input buffer and the VCA. This filter removes the input offset to avoid its amplification by the TGC. An alternative method is to remove the offset effect on the digital domain, either on the device following the ADC or at the ADC output, by using the DIGITAL HIGH PASS FILTER registers (see above).

### <span id="page-20-0"></span>**LOW\_FREQUENCY\_NOISE\_SUPRESSION**

#### Address: 0[11]

low-frequency noise suppression mode is specifically useful in applications where good noise performance is desired in the frequency band of 0MHz to 1MHz (around DC). Setting this mode shifts the low-frequency noise of the ADC in the AFE5851 to approximately fchannel/2, thereby reducing the noise floor around DC to a much lower value.

### **OUTPUT\_DISABLE**

Address: 1[1]

A '1' on this bit sets the outputs into high-impedance state.

### **PATTERN\_MODE**

#### Address: 2[15:13]

AFE5851 can output a variety of test patterns on the LVDS outputs. These test patterns replace the normal ADC data output and help on debugging and synchronization with the device reading the output of the ADC:

- 1. PATTERN\_MODE equal to '000' is the default and disables this test mode, i.e., the output data is the same as the ADC data.
- 2. PATTERN\_MODE equal to '001' (SYNC mode) replaces the normal ADC word by a fixed 111111000000 word.
- 3. PATTERN\_MODE equal to '010' sets the DESKEW mode, where the 12-bit ADC output D<11:0> is replaced with the '101010101010' word, creating a continuous stream of ones and zeros in the data line. The exact sequence (first a zero or a one) depends on power-up. This mode only ensures alternating ones and zeros at the output.
- 4. PATTERN\_MODE equal to '011' will output a constant code set by the bits in CUSTOM\_PATTERN<13:0>. Depending on the value of SERIALIZED\_DATA\_RATE (see below) the output bits follow these rules:
	- (a) On the default case, where SERIALIZED DATA RATE is '00', for a 12-bit ADC data at the output, CUSTOM\_PATTERN<13:2> would be used, replacing the sampled data. These would still be controlled by LSB-first and MSB-first modes in the same way as normal ADC data are.<br>For SERIALIZED\_DATA\_RATE= '01', 10-bit output mode is selected
	- (b) For SERIALIZED\_DATA\_RATE= '01', 10-bit output mode is selected, and bits CUSTOM\_PATTERN<13:4> are used.
	- (c) For SERIALIZED\_DATA\_RATE= '10', 16-bit output mode is selected. On this case, CUSTOM\_PATTERN<13:0> are used for the first 14 most significant bits, and two zeros take the place of the LSBs.
	- (d) For SERIALIZED\_DATA\_RATE= '11', 14-bit mode is selected, and CUSTOM\_PATTERN<13:0> takes the place of the output word.
- 5. PATTERN\_MODE equal to '100' makes it always '1', while setting it to '110' makes the output always '0'.
- 6. PATTERN\_MODE equal to '101' makes the output of the device toggle between all zeros and all ones. On the nth sample clock, the data would be '000000000000' and on the following one (nth+1) it would be '1111111111'.
- 7. PATTERN\_MODE equal to '111' causes all the channels to output a repeating full-scale ramp pattern. The ramp increments from zero code to full-scale code in steps of 1LSB every clock cycle. After hitting the full-scale code, it returns back to zero code and ramps again.

### **PDN\_Channel<7:0>**

#### Address: 1[9:2]

Each bit controls the power down of a pair of consecutive channels (that share the same ADC). For example: PDN Channel<0> powers down channels 1 and 2 and the corresponding LVDS pair become high impedance. DCLK and FCLK are not powered down; they will be active if terminated with 100Ω.

### **PDN\_LVDS**

Address: 2[10:3]

PDN\_LVDS<7..0> selects which LVDS pairs become inactive (zero output). The frame and clock LVDS streams get powerdown only when OUTPUT\_DISABLE or GLOBAL\_PDN are set.

### **REGISTER\_OFFSET\_SUBSTRACTION\_ENABLE**

#### Address: 3[8]

Setting this bit to '1' enables the subtraction of the value on the corresponding OFFSET\_CHANNEL<sub>i</sub><9:2> from the ADC output. The number is specified in 2s complement format. For example, OFFSET\_CHANNEL<sub>i</sub><9:2>='1000000' means "subtract -128". For OFFSET\_CHANNEL<sub>i</sub><9:2>='01111111' the effect will be to subtract 127. Hereby, both addition and subtraction can be done.

Notice that the offset is applied before the digital gain (see next). In fact, digital gain is the last step and the whole data path is 2s complement through out internally. Only when DFS='1' (straight binary output format), the 2s complement word is translated into offset binary right at the end.

### **REGISTER\_READOUT\_ENABLE**

#### Address:0[1]

The device includes an option where the contents of the internal registers can be read back. This may be useful as a diagnostic to verify the serial interface communication between the external controller and the AFE. First, the <REGISTER READOUT ENABLE> bit needs to be set to '1'. Then the user should initiate a serial interface cycle specifying the address of the register (A7-A0) whose content has to be read. The data bits are "don't care". The device will output the contents (D15-D0) of the selected register on the SDOUT pin. The external controller can latch the contents at the rising edge of SCLK. To enable serial register writes, set the <REGISTER READOUT ENABLE> bit back to '0'. The following timing diagram shows this operation (the time specifications follow the same information provided on the table for a serial interface register write):

#### **SERIALIZED\_DATA\_RATE**

#### Address: 3[14:13]

These two bits control the length of the data word, i.e., the number of DCLK per FCLK periods. It is possible, for instance, to output 16bit data stream, even with a 12bit ADC. In this case, the last 4 LSBs are padded with zeros. The pass from higher resolution to lower serialization is not supported though; i.e, it is not possible to select a 10bit stream with a 12bit ADC.

#### **TGC\_REGISTER\_WREN**

Address: 0[2]

Set this bit to '1' to access the TGC table and '0' (default after reset) to access the general purpose register table. As explained before, the same address may point to one bank of registers or to the other. Nevertheless, observe that register 0 of the general purpose registers is always accessible, regardless of the value of TGC\_REGISTER\_WREN. The TGC table starts at address 1.

### **VCA\_LOW\_NOISE\_MODE**

#### Address: 7[10]

Setting this bit to '1' reduces the equivalent input noise of the channel to 5nV/√Hz (for a 31dB gain) at the expense of an increase in power consumption (5mW/channel).

### **TGC CONTROL REGISTER MAP**

The TGC operation is described in the [VGA/TGC](#page-24-0) Operation section below. This section describes the TGC control registers which can be accessed by writing '1' to TGC\_REG\_WREN bit. The following table describes the register map for all the registers involved in the TGC operation.

#### **REG\_VALUE**

Address: 0x01[8:0] to 0x94[8:0]

Each of these 9 bit registers (148 of them) stores the time to stay at a given gain setting, during the gain ramp. The most significant bit of each register (REG\_VALUE<8>) denotes either increment or decrement gain from current gain value. The other 8 bits (REG\_VALUE<7:0>) denote the time (a multiple of 8 x Tclk; Tclk being the channel sampling clock, i.e., double the period of the device input clock) for the change of the gain from the CURRENT\_GAIN to CURRENT\_GAIN  $\pm$ 1dB (depending on the REG\_VALUE<8>). The fastest ramp (shortest time) for this 1dB gain change is set by REG\_VALUE<7:0> equal to 0x00 and it is  $8 \times$  Tclk. The slowest ramp (longest time) for this 1dB gain change is set by REG\_VALUE<7:0> equal to 0xFF and it is 255  $\times$  8  $\times$  Tclk (see VGA operation – described later).

#### **START\_INDEX**

Address: 0x95[7:0]

This 8 bit register specifies/points to the first REG\_VALUE register of the TGC curve (i.e., where the curve starts) and can have values ranging from 1 to 148 (in decimal).

#### **STOP\_INDEX**

#### Address: 0x96[7:0]

This 8 bit register specifies/points to the last REG\_VALUE register of the TGC curve (i.e., where the curve finishes) and can have values ranging from 1 to 148 (in decimal).

# **[AFE5851](http://focus.ti.com/docs/prod/folders/print/afe5851.html)**

SLOS574B –SEPTEMBER 2008–REVISED MAY 2010 **www.ti.com**

### **START\_GAIN**

Address: 0x97[5:0]

This 6 bit register specifies the start gain value from –5dB to 31dB. START\_GAIN = [–5 + REG\_VALUE ] dB

#### **STOP\_GAIN (Not a programmable register, it is an internally computed value)**

Case 1:

INTERP\_ENABLE=1,

STOP\_GAIN = START\_GAIN + (STOP\_INDEX -START\_INDEX) – ( 2 \* Number of decrements) + 0.875dB.

Case 2:

INTERP\_ENABLE='0',

STOP\_GAIN = START\_GAIN + (STOP\_INDEX-START\_INDEX) – ( 2 \* Number of Decrements).

#### **HOLD\_GAIN\_TIME**

Address: 0x98[7:0]

This 8 bit register specifies the time for holding of the STOP\_GAIN, after reaching either the STOP\_GAIN value as computed earlier or the maximum/minimum gain. After this time, the TGC starts stepping down to the START\_GAIN value in 1dB steps every Tclk. The STOP\_GAIN value is held for the following number of clocks:

HOLD\_GAIN\_TIME = [33 \* REG\_VALUE] Tclks

where Tclk is the channel sampling clock.

### **INTERP\_ENABLE**

Address: 0x97[7]

This 8 bit register sets the ramp rate. When INTERP\_ENABLE='1' the ramp rate is 0.125dB for every number of clocks stored in REG\_VALUE:

When INTERP\_ENABLE='0' the ramp rate is 1dB for every 8 times the number of clocks stored in REG\_VALUE:

## **SOFT\_SYNC**

Address 0x99[5]

Setting SOFT SYNC bit to '1' enables the TGC engine to run periodically following a given TGC curve, without the need for a high pulse signal in the SYNC pin (see more details below).

## **UNIFORM\_GAIN\_MODE**

#### Address 0x99[4]

Setting this bit to '0' (default) directs the TGC engine to follow an arbitrary gain versus time curve. If this bit to '1' the gain is ramped up with a slope set by the UNIFORM\_GAIN\_SLOPE register. (See more details below)

#### **UNIFORM\_GAIN\_SLOPE**

Address 0x9B[7:0]

See Uniform Gain Increment Mode section below.

#### **STATIC\_PGA**

Address 0x99[3]

Setting this bit to '1' disables the TGC engine. COARSE\_GAIN and FINE\_GAIN will control the gain value, which will be independent of time.

#### **COARSE\_GAIN**

Address 0x9A[5:0]

This 6 bit register specifies the coarse gain from –5 to 31dB, in 1dB steps. Observe that only values from 0x00 to 0x24, both included, are valid. Setting a value bigger than 0x24 on the COARSE\_GAIN register is the same as setting 0x24. COARSE GAIN =  $[-5 + REG$  VALUE ] dB

#### **FINE\_GAIN**

Address 0x99[2:0]

This 3 bit register specifies the fine gain in steps of 0.125dB resolution, from 0dB to 0.875dB. FINE GAIN =  $[0.125 \times \text{REG}_\text{VALUE}]$  dB

## <span id="page-24-0"></span>**VGA/TGC OPERATION**

The gain variation of the variable gain amplifier (VGA) versus time is called TGC function and on the AFE5851 is controlled digitally. The gain is implemented by a switched network where the switches controlling the gain are synchronized with the ADC sampling instant to minimize glitches on the output data. The gain setting depends on the mode of operation selected by the user. There are 3 possible modes of operation: non-uniform gain, uniform gain, and static mode. The following sections describe each in detail.

**GAIN Profile**

#### SLOS574B –SEPTEMBER 2008–REVISED MAY 2010 **www.ti.com**

**Sync Period**

<span id="page-25-0"></span>given time/sampling instant, the digital gain setting is obtained from an internal memory of 148 positions/registers (named REG\_VALUEs), each 9 bits wide, loaded by the user through the serial port (see Serial Interface section). Addresses 1 to 148 can be used to access these registers, while TGC\_REGISTER\_WREN='1'.

As explained above, the most significant bit of each register (REG\_VALUE<8>) denotes either increment or decrement gain from current gain value. The other 8 bits (REG\_VALUE<7:0>) denote the time (a multiple of 8\*Tclk, being Tclk the sampling clock) for the change of the gain from the CURRENT\_GAIN to CURRENT\_GAIN ±1dB (depending on the REG\_VALUE<8>). The fastest ramp (shortest time) for this 1dB gain change is set by REG\_VALUE<7:0> equal to 0x00 and it is  $8 \times$  Tclk. The slowest ramp (longest time) for this 1dB gain change is set by REG\_VALUE<7:0> equal to 0xFF and it is 255  $\times$  8  $\times$  Tclk.

INTERP\_ENABLE sets the way the gain is increased/decreased. By default the gain ramp is implemented in steps of 1dB (INTERP\_ENABLE equal to 0). If INTERP\_ENABLE is equal to 1, the actual 1dB gain step is implemented in 8 steps of 0.125dB.

The 148 REG\_VALUE registers can be used to store either a single curve or multiple TGC curves. The START\_INDEX register points to the REG\_VALUE register where the TGC curve starts and the STOP\_INDEX register points to the REG\_VALUE register where the TGC curve stops. Using the START\_INDEX and STOP INDEX registers the desired TGC curves can be chosen.

As shown in [Figure](#page-25-0) 34, a pulse high signal on the SYNC pin will set the starting gain value of the TGC curve to the START\_GAIN register value, and it will initiate the progression through the different REG\_VALUEs, starting at START\_INDEX. Observe that there is no option to delay the start of gain stepping after the SYNC pulse is received. Then, the progression continues until either the STOP\_INDEX is reached or maximum/minimum gain is exceeded. After that, the last valid value of gain is held for an extra given number of clocks set by the register HOLD\_GAIN\_TIME.

After the elapsing of clocks mentioned by the HOLD\_GAIN\_TIME register, the TGC starts to step down (or up) to the START\_GAIN in steps of 1dB every Tclk (channel sampling clock) in preparation for the next TGC profile. The TGC will start updating/following the REG\_VALUEs again after a new high pulse on the SYNC pin is given.

The SYNC signal is latched by the rising edge of the channel sampling clock. In other words, the gain increments at the rising edge of the channel sampling clock. Setup time with rising edge is 7ns, and hold time 4ns.

### **SOFT\_SYNC**

The TGC can run periodically following a given TGC curve but without the need for a high pulse signal in the SYNC pin. This is done by setting SOFT\_SYNC bit to '1'. Once this bit is set, the sequence of events is the same as with the hardwired SYNC pulse. The TGC curve updates from START\_INDEX to STOP\_INDEX. After reaching STOP\_INDEX or the maximum/minimum gain, the STOP\_GAIN value is held for HOLD\_VALUE\_TIME and then the gain ramps up or down to START\_GAIN. After this the TGC update starts again automatically and repeats all these steps periodically till the SOFT\_SYNC bit becomes zero.

The SYNC process through register write occurs at the serial clock edge where the register is written. If serial clock and sample clock (channel sampling clock) are synchronous then the described relation in the hardwired SYNC section will hold and the SYNC bit is latched by the rising edge of the channel sampling clock, respecting a setup time with rising edge of 7ns and hold time of 4ns. If sample clock and serial clock are not synchronous then this relationship does not apply and a clock uncertainty of  $\pm 1$  sample will apply in respect to the nearest sample clock rising edge.

Example 1: In the following example of non-uniform gain mode, all the 148 registers are loaded. Nevertheless, the start address for the TGC is set in START\_INDEX to 2 and the stop address (STOP\_INDEX) to 7. The START\_GAIN is set to 6 and HOLD\_GAIN\_TIME is 4.

With a high pulse on the SYNC pin the gain starts from 1dB (START\_GAIN=0x06). 1dB to 2dB ramp is done in 120Tclks, using eight 0.125dB steps (as INTERP\_ENABLE is set to 1), each 15Tclks long. The ramp from 2dB to 3dB is done in 64Tclks, also in 0.125dB steps. The ramp from 3dB to 4dB is done in 40 Tclks. Decrement from 4dB to 3dB in 64Tclks. Gain increment from 3dB to 4dB in 56 Tclks and from 4dB to 4.875dB in 80 Tclks.

Observe that in the case where INTERP\_ENABLE=1, STOP\_GAIN = START\_GAIN + (STOP\_INDEX -START\_INDEX) – ( 2 × Number of decrements) + 0.875dB. In the case where INTERP\_ENABLE='0', STOP\_GAIN = START\_GAIN + (STOP\_INDEX-START\_INDEX) – ( 2 × Number of Decrements). This is due to the fact that the interpolation engine keeps the gain increasing or decreasing when INTERP\_ENABLE=1, while the gain is frozen when INTERP\_ENABLE=0.

#### **Uniform Gain Increment Mode**

By setting UNIFORM GAIN MODE to '1', the TGC engine can also be configured for a uniform increment gain ramp mode where the gain is ramped up from the START GAIN value to the STOP GAIN with a slope set by the UNIFORM\_GAIN\_SLOPE register. Note: STOP\_GAIN is not a programmable register, but just an internally computed value from START\_GAIN, UNIFORM\_GAIN\_SLOPE, START\_INDEX and STOP\_INDEX.

If INTERP\_ENABLE=1, UNIFORM\_GAIN\_SLOPE sets the number of Tclk (channel sampling clock) at a given gain before incrementing or decrementing 0.125dB. If INTERP\_ENABLE=0, this register sets the number of 8\*Tclk (eight sampling periods) at a given gain before incrementing or decrementing 1dB. Observe that in both cases the time it takes to step by 1dB is the same. In INTERP ENABLE=0 the gain is stationary at the same setting for the given time, while in the other case the gain increments in fine gain steps of 0.125dB to cover that 1dB step

When INTERP\_ENABLE is zero, the STOP\_GAIN is computed as START\_GAIN (STOP\_INDEX-START\_INDEX). Nevertheless, when INTERP\_ENABLE = '1', the STOP\_GAIN is equal to START\_GAIN + (STOP\_INDEX - START\_INDEX) + 0.875dB. This is basically due to the fact that the interpolation engine keeps the gain increasing on the second case, while, as explained above, is frozen on the first case. Observe that START INDEX and STOP INDEX are not used in this case as pointers to the REG VALUEs table. Instead, only the difference between the two is important to compute STOP GAIN. As such, START\_INDEX can be set to zero and STOP\_INDEX will store STOP\_GAIN – START\_GAIN. Observe that only positive slope ramps are possible.

Example 1: setting START\_GAIN=0x2 (-3dB), START\_INDEX=0x00, STOP\_INDEX=0x06, INTERP\_ENABLE=0 and UNIFORM\_GAIN\_SLOPE=0x8, will set the gain at  $-3dB$  for  $8 \times 8 \times$  Tclk, then to  $-2dB$  for another 64 Tclk, and so on, through –1, 0, 1, 2 and 3. After spending  $64 \times$  Tclk in 3dB, the gain will stay at that gain setting for HOLD GAIN TIME and start stepping down back to START GAIN, with 1dB per Tclk.

Example 2: for the same settings, START\_GAIN=0x2 (–3dB), START\_INDEX=0x00, STOP\_INDEX=0x06, and UNIFORM\_GAIN\_SLOPE=0x8, if we set INTERP\_ENABLE=1, the gain will start at -3dB for 8Tclk, then –2.875dB for another 8Tclk, then –2.750dB and so on, till 3dB. At this point, while in example 1, with INTERP\_ENABLE=0 the gain would be frozen for another 64 Tclk, in this example, the gain will continue to increase with 0.125dB steps every 8Tclk till 3.875dB is reached. There will stay for another 8Tclk before starting to wait for HOLD\_GAIN\_TIME and start stepping down.

Example 3: for START\_GAIN=0x2(–3dB) , START\_INDEX=0x00, STOP\_INDEX=0x00, INTERP\_ENABLE=1 and UNIFORM GAIN SLOPE=0x1, the gain will step through  $-3dB$ ,  $-2.875$ ,  $-2.75$ ,  $-2.625$ ,  $-2.5$ ,  $-2.375$ ,  $-2.25$  and –2.125, staying at each of these 8 values 1 clock cycle (8 total). Then it will wait for HOLD\_GAIN\_TIME in –2.125dB and then it will start stepping down back to –3dB.

Example 4: same settings as example 3, but with INTERP\_ENABLE=0, would simply set the VGA gain to –3dB for 8 clock cycles and then the logic would wait for HOLD\_GAIN\_TIME.

#### **Static PGA Mode**

The 3rd mode of operation is actually a mode where the TGC engine is disabled by writing '1' into the STATIC\_PGA bit. This enables the use of a fixed gain mode where the gain is obtained by the sum of a coarse and a fine gain. Coarse gain can be set from –5 to 31dB, in 1dB steps, by the register COARSE\_GAIN (6 bit word from 0x00 to 0x24). Setting a value bigger than 0x24 on the COARSE\_GAIN register is the same as setting 0x24. The fine gain can be set in steps of 0.125dB resolution, from 0dB to 0.875dB by the FINE\_GAIN register (3 bit word with range from 0x00 to 0x07). Observe that the maximum gain, when both registers are set to their maximum gains, is actually 31.875dB.

### **ANTI ALIAS FILTER (AAF)**

The AFE5851 integrates a selectable 3 order low pass filter for each of the 16 channels. The cutoff frequency can be set for all the channels simultaneously through the serial interface (see FILTER\_BW register, in the General Purpose Register table) between 3 possible settings: 7.5, 10 and 14MHz. [Figure](#page-10-0) 19 shows the frequency response for each of these settings. The filter characteristics are set by passive components which are subject to variations over process and temperature. A typical variation of  $\pm 5\%$  on the frequency characteristics is expected.

### **CLAMPING CIRCUIT AND OVERLOAD RECOVERY**

The AFE5851 is designed in particular for ultrasound applications where the front-end device is required to recover very quickly from an overload condition. Such overload can either be the result of a transmit pulse feed-through or a strong echo, which can cause overload of the VGA and ADC.

Enabled by default, the AFE5851 includes a clamping circuit to further optimize the overload recovery behavior of the complete channel (see [Figure](#page-15-0) 31). The circuit can be disabled by writing a '1' in the bit 14 of the address 70 (decimal) of the General Purpose Register Map. The clamp is set to limit the signal at 3dB above the full scale of the ADC (2Vpp).

### <span id="page-28-0"></span>**CLOCK INPUTS**

The 16 channels on the device operate from a single clock input. To ensure that the aperture delay and jitter are the same for all channels, the AFE5851 uses a clock tree network to generate individual sampling clocks to each channel. The clock channels for all the channels are matched from the source point to the sampling circuit of each of the eight internal ADCs. The variation on this delay is described in the Aperture Delay parameter of the Output Interface Timing. Its variation over time is described in the Aperture Jitter number of the same table. Observe that the rising edges of the input clock are used to sample the even channels in one input clock period and the odd channels in the next. Using an input clock double the speed of the channel sampling clock ensures that the sampling instant between even and odd channels is exactly an input clock period apart and does not depend on its duty cycle..

The AFE5851 clock input can be driven differentially (sinewave, LVPECL or LVDS) or single-ended (LVCMOS). The clock input of the device has an internal buffer/clock amplifier (see [Figure](#page-28-1) 35) which is enabled or disabled automatically depending on the type of clock provided (autodetect feature). When enabled, the device will consume 6mW more power from the AVDD18 supply rail, but it will also accept differential or single ended inputs of smaller swing.

<span id="page-28-1"></span>

If the preferred clocking scheme for the device is single-ended, CLKINM pin should be connected to ground, i.e., shorted directly to AVSS (see [Figure](#page-29-0) 37). In this case, the autodetect feature will shut down the internal clock buffer and the device will go into single-ended clock input automatically. The user should connect the single-ended clock source directly (no decoupling) to CLKINP pin, which would be the only device clock input. In that case, it is recommended the use of low jitter square signals (LVCMOS levels, 1.8V amplitude) to drive the ADC (see [SLYT075](http://www.ti.com/lit/pdf/www.ti.com) for further details on the theory).

For single ended sinusoidal clocks or for differential clocks (differential sinewave, LVPECL, LVDS…), the clock amplifier should be enabled. For that, the connection scheme of [Figure](#page-29-1) 36 should be used. The common-mode voltage of the clock source should match one of the clock inputs of the AFE5851 (VCM) which is set internally using 5kΩ resistors, as shown in [Figure](#page-28-1) 35. The easiest way to ensure this is to AC couple the inputs as shown in [Figure](#page-29-1) 36. The same scheme applies to the case where the clock is single ended but its amplitude is small or its edges are not sharp (for instance, with a sinusoidal single-ended clock). In this case, the input clock signal can be connected with a capacitor to CLKINP (as in [Figure](#page-29-1) 36) and the CLKINM should be connected to ground also through a capacitor, i.e., AC coupled to AVSS.

**Figure 36. Differential Clock Driving Circuit**

<span id="page-29-1"></span><span id="page-29-0"></span>If a transformer is used with the secondary floating (for instance, to pass from single-ended to differential) , it can then obviously be connected directly to the clock inputs, without the need of the 100nF series capacitors.

**Figure 37. Single-Ended Clock Driving Circuit**

Finally, on the differential clock configurations, [Figure](#page-30-0) 38 shows the use of the CDCM7005 to generate the AFE5851 clock signals.

**Figure 38. PECL Clock Drive Using CDCM7005**

#### <span id="page-30-0"></span>**DIGITAL OUTPUTS**

The conversion results from all 8 ADCs are serialized and output using one LVDS data pair per ADC, at 12 times the device input clock rate. Besides that, two more LVDS pairs are used to facilitate the interface to the circuit reading the ADC output. For one side, a reference frame LVDS signal running at the channel rate (half the input clock rate) indicates the beginning and end of the sample word. On top of that, the device outputs a reference clock running at 6 times the input clock rate, with rise and fall times aligned with the individual bits. See the Output Interface Timing section for a description of the timing diagram as well as details on the timing margins.

[Figure](#page-31-0) 39 represents the device LVDS output circuit. Observe that for an LVDS output high (OUTP=1.375V, OUTM=1.025V) the "high" switches would be closed and the "low" switches would be open. For LVDS output low (OUTP=1.025V, OUTM=1.375V) the "low" switches would be closed and the "high" left open. As the "high" and "low" switches have a nominal R<sub>ON</sub> of 50Ω ±10%, notice that the output impedance will be nominally 100Ω in any of those two configurations ("high" or "low" switches closed).

**Figure 39. LVDS Output Circuit**

# <span id="page-31-0"></span>**EXTERNAL/INTERNAL REFERENCE**

See EXTERNAL\_REFERENCE register description in the General Purpose Register Description Section.

# **POWER SUPPLIES**

The use of low noise power supplies with adequate decoupling is recommended, being the linear supplies the first choice vs switched ones, which tend to generate more noise components that can be coupled to the AFE5851.

There is no need of any type of power-up sequencing, although a positive pulse must be applied to the Reset pin once the power supplies are considered stable (see Serial Interface Section)

There are several types of powerdown modes. On the standby mode all circuits but the reference generator are powered-down. This enables for a fast recovery from power down to full operation. On the full power down mode, all the blocks are powered down (except some digital circuits). The power savings are bigger but the power-up will also be slower (see specification tables for more details). The device includes also the possibility of powering down pairs of channels (corresponding to the same ADC) through the use of PDN\_Channel<7:0> and powering down the LVDS outputs by using PDN\_LVDS.

Finally, notice that the metallic heat sink under the package is also connected to analog ground.

# **LAYOUT INFORMATION**

The evaluation board represents a good guideline of how to layout the board to obtain the maximum performance out of the AFE5851. General design rules as the use of multilayer boards, single ground plane for both, analog and digital ADC ground connections, and local decoupling ceramic chip capacitors should be applied. The input traces should be isolated from any external source of interference or noise, including the digital outputs as well as the clock traces. Clock should also be isolated from other signals although the low frequencies of the input signal relaxes the jitter requirements.

In order to maintain proper LVDS timing, all LVDS traces should follow a controlled impedance design (for example, 100Ω differential). In addition, all LVDS trace lengths should be equal and symmetrical. It is recommended to keep trace length variations less than 150mil (0.150in or 3.81mm).

It is necessary to solder the exposed pad at the bottom of the package to a ground plane for best thermal performance. For detailed information, see application notes QFN Layout Guidelines [\(SLOA122A](http://www.ti.com/lit/pdf/www.ti.com)) and QFN/SON PCB Attachment [\(SLUA271A\)](http://www.ti.com/lit/pdf/www.ti.com).

## **DEFINITION OF SPECIFICATIONS**

**Analog Bandwidth –** The analog input frequency at which the power of the fundamental is reduced by 3 dB with respect to the low frequency value.

**Aperture Delay –**The delay in time between the rising or the falling edge of the input sampling clock (depending on the channel) and the actual time at which the sampling occurs. This delay will be different across channels. The maximum variation is specified as aperture delay variation (channel-channel).

**Aperture Uncertainty (Jitter) –** The sample-to-sample variation in aperture delay.

**Clock Pulse Width/Duty Cycle –** The duty cycle of a clock signal is the ratio of the time the clock signal remains at a logic high (clock pulse width) to the period of the clock signal. Duty cycle is typically expressed as a percentage. A perfect differential sine-wave clock results in a 50% duty cycle.

**Maximum Conversion Rate –** The maximum sampling rate at which certified operation is given. All parametric testing is performed at this sampling rate unless otherwise noted.

**Minimum Conversion Rate –** The minimum sampling rate at which the ADC functions.

**Differential Nonlinearity (DNL) –** An ideal ADC exhibits code transitions at analog input values spaced exactly 1 LSB apart. The DNL is the deviation of any single step from this ideal value, measured in units of LSBs.

**Integral Nonlinearity (INL) –** The INL is the deviation of the ADC's transfer function from a best fit line determined by a least squares curve fit of that transfer function, measured in units of LSBs.

**Gain Error –** The difference between the actual gain of a channel & its ideal (theoretical) gain, i.e., the error in the absolute gain of the channel.

**Gain Matching –** The gain difference between two channels with same theoretical gain setting. For perfect matching, the difference should be zero. On the context of this device, the gain matching is obtained in two different ways:

- 1. The values on the specification table represent the expected gain matching between any two channels on the system. The gain is measured on every channel of every device, for a given gain setting, at any temperature. The difference between the maximum recorded gain and the minimum recorded gain represents the gain matching at that given gain setting. The same is done for every gain setting and the maximum difference for any gain setting is presented on the table.
- 2. The gain matching histogram represents the channel to channel matching inside the same device, i.e., the maximum expected gain difference between any two channels of the same device, or in other words, the peak-to-peak variation of absolute gains across all channels in the device. At a given gain setting for all the channels of a given device (at one temperature assumed common to the whole device), the difference between the channel with maximum gain and the channel with minimum gain represents one count. The same thing is done for all the devices and for 3 temperatures (–40C, 25C and 85C). Every measurement of a device at one given temperature represents one count.

**Offset Error –** The offset error is the difference, given in mV, between the ADC's actual average idle channel output code and the ideal average idle channel output code.

**Temperature Drift –** The temperature drift coefficient (with respect to gain error and offset error) specifies the change per degree Celsius of the parameter from  $T_{MIN}$  to  $T_{MAX}$ . It is calculated by dividing the maximum deviation of the parameter across the  $T_{MIN}$  to  $T_{MAX}$  range by the difference  $T_{MAX}-T_{MIN}$ .

**Signal-to-Noise Ratio –** SNR is the ratio of the power of the fundamental (PS) to the noise floor power (PN), excluding the power at DC and the first nine harmonics.

$$
SNR = 10\text{Log}10\frac{\text{P}_S}{\text{P}_N} \tag{1}
$$

SNR is either given in units of dBc (dB to carrier) when the absolute power of the fundamental is used as the reference, or dBFS (dB to full scale) when the power of the fundamental is extrapolated to the converter's full-scale range.

**Signal-to-Noise and Distortion (SINAD) – SINAD is the ratio of the power of the fundamental**  $(P_S)$  **to the power** of all the other spectral components including noise  $(P_N)$  and distortion  $(P_D)$ , but excluding dc.

Copyright © 2008–2010, Texas Instruments Incorporated Submit [Documentation](http://www.go-dsp.com/forms/techdoc/doc_feedback.htm?litnum=SLOS574BB&partnum=AFE5851) Feedback 33

**NSTRUMENTS** 

**EXAS** 

$$
SINAD = 10 \log 10 \frac{P_S}{P_N + P_D}
$$

SINAD is either given in units of dBc (dB to carrier) when the absolute power of the fundamental is used as the reference, or dBFS (dB to full scale) when the power of the fundamental is extrapolated to the converter's full-scale range.

**Effective Number of Bits (ENOB) –** The ENOB is a measure of a converter's performance as compared to the theoretical limit based on quantization noise.

$$
ENOB = \frac{SINAD - 1.76}{6.02}
$$

(3)

(2)

**Spurious Free Dynamic Range (SFDR) –** SFDR is the ratio of the power of the fundamental (PS) to the highest FFT bin, harmonic or not, excluding DC. SFDR is typically given in units of dBc (dB to carrier).

**Second Harmonic Distortion (HD2) –** HD2 is the ratio of the power of the fundamental (PS) to the second harmonic, typically given in units of dBc (dB to carrier).

**Third Harmonic Distortion (HD3) –**HD3 is the ratio of the power of the fundamental (PS) to the third harmonic, typically given in units of dBc (dB to carrier).

**Total Harmonic Distortion (THD) – THD** is the ratio of the power of the fundamental  $(P_s)$  to the power of the first nine harmonics (PD).

$$
THD = 10 \log 10 \frac{P_S}{P_D}
$$

THD is typically given in units of dBc (dB to carrier).

**AC Power Supply Rejection Ratio (AC PSRR) –** A measure of the device immunity to variations in its supply voltage. In this datasheet, if ΔVSUP represents the change in supply voltage and ΔVOUT is the resultant change of the ADC output code (referred to the input), then:

$$
PSRR = 20 \log \left( \frac{\Delta V \text{out}}{\Delta V \text{sup}} \right)
$$

# **PACKAGE MATERIALS INFORMATION**

\*All dimensions are nominal

Pack Materials-Page 2

# **GENERIC PACKAGE VIEW**

# **RGC 64 VQFN - 1 mm max height**

**9 x 9, 0.5 mm pitch** PLASTIC QUAD FLATPACK - NO LEAD

Images above are just a representation of the package family, actual package may vary. Refer to the product data sheet for package details.

# **PACKAGE OUTLINE**

# **RGC0064H VQFN - 1 mm max height**

PLASTIC QUAD FLATPACK - NO LEAD

NOTES:

- 1. All linear dimensions are in millimeters. Any dimensions in parenthesis are for reference only. Dimensioning and tolerancing per ASME Y14.5M.
- 2. This drawing is subject to change without notice.
- 3. The package thermal pad must be soldered to the printed circuit board for thermal and mechanical performance.

# **EXAMPLE BOARD LAYOUT**

# **RGC0064H VQFN - 1 mm max height**

PLASTIC QUAD FLATPACK - NO LEAD

NOTES: (continued)

4. This package is designed to be soldered to a thermal pad on the board. For more information, see Texas Instruments literature number SLUA271 (www.ti.com/lit/slua271).

5. Vias are optional depending on application, refer to device data sheet. If any vias are implemented, refer to their locations shown on this view. It is recommended that vias under paste be filled, plugged or tented.

# **EXAMPLE STENCIL DESIGN**

# **RGC0064H VQFN - 1 mm max height**

PLASTIC QUAD FLATPACK - NO LEAD

NOTES: (continued)

6. Laser cutting apertures with trapezoidal walls and rounded corners may offer better paste release. IPC-7525 may have alternate design recommendations.
